Appendix I: Monte Carlo Experiment to Verify Appropriateness of Exponentiating Combined Coefficient Confidence Bounds

In order to verify that accurate confidence bounds can be located for relative hazards by exponentiating those of a combined coefficient, I demonstrate below with table A1 that the distribution of the combined coefficient and relative hazard will correspond to each other at the same values of the modifying variable and estimated coefficients. For this table, I drew a random sample of 50 $\hat{\beta}$ assuming a joint normal distribution with mean vector [.5 -.2] and variance of $\begin{bmatrix} .04 & -.001 \\ -.001 & .02 \end{bmatrix}$. To further demonstrate the appropriateness of this method, I used the same distribution to draw 1,000 $\hat{\beta}$ for each of 10 values of the modifying variable x_2 . I utilized this simulated sampling distribution to compare the confidence intervals derived from a sampling technique to those from the exponentiation of the combined coefficient. Figure A1 displays the result of this test. As the reader can see, there is a slight, though not statistically significant, difference between the median calculated relative hazard and the exponentiated mean of the combined coefficient. The confidence intervals from the two methods, however, match up exactly when a sufficiently large number of draws is taken from the distribution of the coefficient estimates.

Table A1. Simulated Distribution of Combined Coefficient and Relative Hazard

Obs.	x_2	$\hat{\beta}_1$	$\hat{\beta}_2$	Combined Coefficient ($\hat{\beta}_1 + \hat{\beta}_2 x_2$)	Combined Coefficient Percentile	Relative Hazard ($e^{\hat{\beta}_1 + \hat{\beta}_2 x_2}$)	Relative Hazard Percentile

Figure A1. Comparison of Methods for Obtaining Confidence Intervals around Relative Hazard

NOTE: Simulated data of 10,000 draws of beta1 and beta1 from mean vector of [.5, -.2] and covariance matrix of [.04, -.001 \ -0.001, .02]

Appendix II: Sample STATA Code

The code below provides generic examples for producing the measures described in the text: the combined coefficient, the relative hazard, the hazard ratio and the first difference. For combined coefficients and relative hazards, simulation procedures are unnecessary as the simple formula for variance of summed random variables applies.

For the simulation procedures, when values of survival time are very numerous, it may be desirable to select key values rather than making the calculation at every point in time as the time required for the simulation procedure increases dramatically with the size of the dataset being used. An interesting alternative option would be to create a variable which tags the percentiles of time. The original data can then be collapsed to the mean values of time within each percentile. This would be accomplished easily with the following Stata commands:

```
xtile time = _t, n(100)
collapse (mean) _t, by(time)
```

Aside from saving time, this approach will also preserve the distribution of survival times, which will allow the analyst to array the resultant measures of substantive effect against the density of actual observations. Some nuance will be lost by calculating the effect at only key points, and the resulting plots of the statistics will not be smooth.

In the code, carrot brackets (<>) indicate items which should be filled in by the programmer. These include variable names and numerical values particular to the analysis at hand. For example, if the NPH-violating effect stems from the variable *age* and a new variable for the interaction with time is named *ageXlntime*, then the item `_b[<X>]` below should be filled in `_b[age]` and the item `_b[<X*ln(_t)>]` should be filled in `_b[ageXlntime]`. The items `v[<#, #>]` refer to elements in the variance-covariance matrix, where the first # should be filled in with the row number and the second # should be filled in with the column number.
